The stability and control of rotors at high advance ratio are considered. Teetering, articulated, gimbaled, and rigid hub types are considered for a compound helicopter (rotor and fixed wing). Stability predictions obtained using an analytical rigid flapping blade analysis, a rigid blade CAMRAD II model, and an elastic blade CAMRAD II model are compared. For the flapping blade analysis, the teetering rotor is the most stable, showing no instabilities up to an advance ratio of 3 and a Lock number of 18. With an elastic blade model, the teetering rotor is unstable at an advance ratio of 1.5. Analysis of the trim controls and blade flapping shows that for small positive collective pitch, trim can be maintained without excessive control input or flapping angles.

## Nomenclature

$k_p$	blade pitch-flap coupling ratio
$\beta$	rigid blade flap angle
$\gamma$	Lock number
$\delta_3$	blade pitch-flap coupling angle
$\nu_\beta$	fundamental flapping frequency
$\omega$	dominant blade flapping frequency
$\mu$	rotor advance ratio
$\nu_\theta$	blade fundamental torsion frequency
( )	derivative with respect to azimuth

## Introduction

Recently there has been increased interest in expanding the envelope of rotorcraft, particularly in terms of speed, altitude and range. Increased range allows attack, scout, and rescue aircraft to reach farther from their bases. Additional speed and altitude capability increases the survivability of military vehicles and cost efficiency of civilian aircraft. Long loiter times improve the effectiveness of scout aircraft, with particular applications of interest being unmanned aerial vehicles (UAVs) and homeland security surveillance aircraft.

Much work has been focused on tilt rotor aircraft: both military and civilian tilt rotors are currently in development. But other configurations may provide comparable benefits to tilt rotors in terms of range and speed. Two such configurations are the compound helicopter and the autogyro. These

configurations provide short takeoff or vertical takeoff capability, but are capable of higher speeds than a conventional helicopter because the rotor does not provide the propulsive force. At high speed, rotors on compound helicopters and autogyros with wings do not need to provide the vehicle lift. The drawback is that redundant lift and/or propulsion systems add weight and drag which must be compensated for in some other way.

One of the first compound helicopters was the McDonnell XV-1 "Convertiplane," built and tested in the early 1950s. There are many novel design features in this remarkable aircraft (Refs. 1-4), which was tested in the NACA 40- by 80-Foot Wind Tunnel at the Ames Aeronautical Laboratory (Ref. 5) and flight tested near McDonnell's St. Louis, Missouri facilities (Ref. 6). The aircraft successfully flew in its three distinct operating modes, helicopter, autogyro, and airplane, and could transition smoothly between them.

One of the features of the XV-1 was that in airplane mode, the rotor would be slowed to a significantly lower speed to reduce its drag in forward flight. The combination of high forward speed and low rotor speed produced an advance ratio near unity, which is far above what is typical for conventional edgewise rotors.

Other prototype compound helicopters since the XV-1 include the Fairey Rotodyne and the Lockheed Cheyenne. Prototypes of both aircraft were built and flown, but never entered production. Recently, CarterCopters and Groen Brothers have developed autogyro demonstrators and have proposed autogyros and compound helicopters for future heavy lift and unmanned roles.

Previously, the performance of slowed-rotor compound aircraft was examined with isolated rotor and rotor plus fixed

wing analytical models (Ref. 7). The purpose of the current effort in the Aeroflightdynamics Directorate of the US Army Aviation and Missile Research, Development and Engineering Center is to examine the stability of slowed-rotor compound aircraft, particularly at high advance ratios.

In the present study, rigid blade flapping stability is examined with a simplified analysis and with the comprehensive analysis CAMRAD II. Elastic blade stability is also calculated with CAMRAD II. Finally, performance and trim are examined for teetering, articulated, and rigid rotors.

### Flap Stability

The simplified analysis predictions are based on rigid flapping blade equations similar to those developed by Sissingh (Ref. 8). These equations were used by Peters and Hohenemser (Ref. 9) to examine flapping stability of an isolated blade and a four-bladed gimbaled rotor with tilt-moment feedback. Here, they are used to compare different hub configurations in order to assess suitability for high advance ratio operation.

The analysis addresses only rigid blade flapping; lag and torsion motion are not modeled. The aerodynamics are linear and aerodynamic coefficients are obtained by integrating analytically along the blade length. The flapping blade equations are integrated over a single rotor revolution and Floquet theory is used to determine the system stability. The homogeneous flapping blade equation is given by

$$\ddot{\beta} - \gamma M_{\beta} \dot{\beta} + (v_{\beta}^2 - \gamma M_{\beta} + \gamma k_p M_{\theta}) \beta = 0 \quad (1)$$

In this expression,  $M_{\beta}$ ,  $M_{\theta}$ , and  $M_{\theta}$  are the aerodynamic coefficients. The blade motion is thus defined by only the flap frequency, Lock number, advance ratio (embedded in the aerodynamic coefficients) and pitch-flap coupling. The pitch-flap coupling ratio and the more commonly used  $\delta_3$  angle are related by

$$k_p = \tan \delta_3 \quad (2)$$

For the present study, multi-blade equations were derived for articulated and gimbaled (three bladed) rotors, as well as teetering and an XV-1-type gimbaled rotor. The latter two configurations were not addressed in Ref. 9. The teetering and gimbaled rotors are straightforward. The teetering rotor has only a single degree of freedom for the teeter motion: coning is not allowed. For the gimbaled rotor, there are two cyclic degrees of freedom and a coning degree of freedom.

The XV-1 rotor is more complicated. It has a three-bladed gimbaled rotor with offset coning hinges. The gimbal motion has a flap frequency of  $v_{\beta} = 1/\text{rev}$  and pitch-flap coupling angle  $\delta_3 = 15$  deg. The coning motion has a flap frequency of

$v_{\beta} = 1.1/\text{rev}$  and  $\delta_3 = 65.6$  deg. To model the XV-1 rotor in the context of the simplified analysis, the appropriate constants were used in each of the multi-blade equations. For the two cyclic equations,  $v_{\beta} = 1/\text{rev}$  and  $\delta_3 = 15$  deg were used, and for the coning equation,  $v_{\beta} = 1.1/\text{rev}$  and  $\delta_3 = 65.6$  deg were used.

A series of stability maps for an articulated rotor with flap frequency  $v_{\beta} = 1/\text{rev}$  is shown in Fig. 1. In each plot, the damping contours are shown as solid lines, positive numbers indicating positive damping, and negative numbers indicating an instability. Only the damping of the least stable root is shown. The dashed lines separate regions where the dominant frequency of the root is  $1 \pm n/\text{rev}$ ,  $0.5 \pm n/\text{rev}$ , or non-harmonic frequencies. Dominant system frequencies of  $1/\text{rev}$  and  $0.5/\text{rev}$  occur when the Floquet roots are on the real axis, whereas the frequency is non-harmonic when the roots are complex conjugates.

Specific frequencies are identified by solving the flapping equation in hover, where the coefficients are constant rather than periodic. The roots of the system are given by

$$s = -\frac{\gamma}{16} \pm i \sqrt{v_{\beta}^2 + \frac{\gamma}{8} k_p - \left(\frac{\gamma}{16}\right)^2} \quad (3)$$

The frequency,  $\omega$ , is the imaginary part, and can be solved for  $\gamma$  as

$$\gamma = 16 \left( k_p \pm \sqrt{k_p^2 + v_{\beta}^2 - \omega^2} \right) \quad (4)$$

The hover Lock numbers for a blade frequency  $v_{\beta}$  of 1.0 are given in Table 1. Missing Lock numbers indicate that the roots are complex numbers.

The pitch-flap coupling varies from 0 to 65.6 deg in the four plots. The 65.6 deg angle was chosen because the coning hinges on the XV-1 have 65.6 deg of  $\delta_3$ . Increasing  $\delta_3$  (Figs. 1a-c) increases the flapping stability margin such that at  $\delta_3$  of 30 deg, there is no unstable region in this range of advance ratio and Lock number. Once  $\delta_3$  exceeds about 45 deg, the damping at high advance ratio declines again. Fig. 1d shows  $\delta_3$  of 65.6 deg and includes several unstable regions with the stability boundary occurring at a lower advance ratio than  $\delta_3 = 0$  (Fig. 1a). The plots suggest that an articulated blade can be used at advance ratios higher than 2 if appropriate  $\delta_3$  is included.

Stability maps for a teetering rotor are shown in Fig. 2. The teetering rotor stability is quite different from that of the articulated blade. The stability is much less dependent on advance ratio throughout the entire  $\delta_3$  and Lock number range. The effect of  $\delta_3$  on damping is also much less pronounced than in the single blade case. The damping magnitudes change with changes in  $\delta_3$ , but the characteristic shape remains the same. The damping is level or slightly increasing up to an advance

Table 1. Hover Lock numbers for a rotor with flap frequency  $\nu_\beta = 1.0$

$k_p$	$\delta_3$	$\omega = 0$	$\omega = 0.5$	$\omega = 1.0$	$\omega = 1.5$	$\omega = 2.0$	$\omega = 2.5$
0	0	16	13.9	0	-	-	-
0.268	15	20.9	18.8	8.6	-	-	-

Fig. 2. Stability maps of a rigid blade teetering rotor at 0, 15, 30, and 65.6 deg of  $\delta_3$ .

ratio of unity, then gradually decreases at higher advance ratios. This simple analysis suggests that a teetering rotor is a good candidate for a high advance ratio rotor.

Results for a rigid gimbaled rotor are shown in Fig. 3. For these results, a 3-bladed rotor with only the gimbal motion (specifically two cyclic modes) is considered. Like the articulated and teetering rotors, the flap frequency is  $v_{\beta} = 1.0$ . From these plots, an advance ratio limit near  $\mu = 2$  is evident. For no pitch flap coupling, Fig. 3a, an instability occurs around  $\mu = 1.5$ . Increasing  $\delta_3$  to 15-30 deg delays the onset of this instability to about  $\mu = 2$  (Fig. 3b-c), but additional  $\delta_3$  does not delay the onset further (Fig. 3d). This suggests that an inherent limit exists that can only be alleviated slightly with  $\delta_3$ , at least without coning motion.

A production gimbaled rotor would not be rigid in coning. It would either have coning hinges, like the XV-1, or it would have a coning mode due to elastic bending of the blades. In either case, the coning mode would have a frequency greater than 1. The coning mode of a 3-bladed gimbaled rotor is shown in Fig. 4. For this plot, the coning equation which was neglected for Fig. 3 was solved separately. To match the coning mode of the XV-1, the flap frequency for these plots has been increased to  $v_{\beta} = 1.1$ .

For this mode, no instability is seen for any of the plots. The damping contours are relatively independent of advance ratio, and change very little with increasing  $\delta_3$ . Although the frequency contours change dramatically with  $\delta_3$ , the damping contours appear to change only in the vicinity of the frequency boundaries.

The stability map for the XV-1 rotor is shown in Fig. 5. If there were no coupling between the gimbal and coning modes, this plot would be the combination of Figs. 3b and 4d. There are two large instability regions, the high Lock number region with a 0.5/rev frequency, and the low Lock number region, whose frequency is not locked to 0.5/rev or 1/rev. The low Lock number region extends down to an advance ratio of about 1.4. The Lock number at this minimum point is very close to the 4.2 Lock number of the XV-1.

Ref. 3 identified a 0.5/rev instability in a test model at  $\mu \approx 1.5$ . Such a stability boundary agrees well with the current prediction, but the frequencies do not agree. The thin areas enclosed by the dashed lines in the lower right of Fig. 5 are frequency locked at 0.5/rev, but outside these small regions the frequency is not locked.

### CAMRAD II Teetering Rotor Model Description

The flapping blade analysis provides a broad picture of the stability of a number of rotor configurations. Lock numbers, and advance ratios, but is limited in usefulness by its many simplifications. To go beyond the guidance provided by the flapping blade analysis, a slowed-rotor vehicle model based on the CarterCopter Technology Demonstrator, or CCTD (Ref. 10),

was developed for the comprehensive analysis CAMRAD II (Ref. 11). The model was previously used to examine the performance (Ref. 7) of the slowed-rotor concept and in the present study is used to examine stability and control. Since little detailed information is publicly available about the prototype, the analytical model is relatively simple. It is intended only to capture the basic geometries of the rotor and wing of the aircraft (see Fig. 6). The maximum gross weight of the demonstrator is approximately 4200 lb.

Both rigid blade and elastic blade models were developed. The models were developed to investigate parameter variations applicable to slowed-rotor vehicles in general rather than to model the CCTD design specifically in detail. The rigid blade analysis does not allow for elastic bending or torsion, so many details of the mass and stiffness distributions and aerodynamic center offsets are unnecessary. For the elastic blade analysis, the rotor was made as simple as possible to avoid introduction of additional unknowns into the results. The properties of the rotor and wing are shown in Table 2.

The CCTD prototype rotor has an extremely low Lock number caused by the presence of a 65 lb mass in each blade tip. These masses provide rotational inertia to store enough energy in the rotor for a jump take-off. For the present study, variations in chordwise offset of masses were not considered. The tip masses were placed on the quarter chord for both the rigid and elastic blade models.

For the actual aircraft, the blade airfoil changes from an NACA 65,021 at the root to an NACA 65006 at the tip. Airfoil tables were not available for either of these sections, so the NACA 23012 was used as a substitute.

The wing model is straightforward. The wing is swept, tapered, and untwisted, with an aspect ratio of 13.4. The aerodynamic model of the wing in CAMRAD II is identical to the aerodynamic model of the rotor blades. The only modeling detail to note at present is again the use of the NACA 23012 airfoil as a replacement for the NACA 65,618 used on the prototype.

Before discussing trim, some definitions should be noted. The CCTD is an autogyro, so while it is flying, there is no torque applied to the rotor shaft. The XV-1 also operated in this mode at high speed. In the context of this paper, the word *autorotation* describes the trim state of the rotor, where rotor speed is maintained with no torque input to the shaft. For a helicopter, autorotation of the rotor implies that an emergency landing is in process, but for an autogyro, the rotor is in an autorotation state for normal cruise flight. These should not be confused. *Rotor power*, when used in reference to an autorotating rotor, is defined as the rotor drag multiplied by its velocity. This power is indirectly supplied by the aircraft's propulsion system (which overcomes the drag) and not shaft torque.

Several trim variables were used. The CCTD is controlled only with collective pitch and tilt of the spindle to which the

Fig. 4. Stability maps of only the coning mode of a rigid blade gimbaled rotor with coning hinge at 0.062R and 0, 15, 30, and 65.6 deg of  $\delta_3$ ,  $v_B = 1.1$ .

Fig. 5. Stability map for XV-1 rotor,  $\delta_{3,g} = 15$  deg  $\delta_{3,c} = 65.6$  deg,  $v_{\beta,c} = 1.1$ ,  $v_{\beta,g} = 1.0$ .

rotor is attached. For the calculations, spindle tilt was modeled by tilting the rotor shaft. If the rotor is trimmed in autorotation, the shaft torque must be zero. The spindle tilt was used to control the shaft torque. The incidence angle of the wing was used to trim the vehicle lift. By using wing incidence and spindle tilt, the controls are largely independent of each other. Shaft angle affects both rotor lift and shaft torque, but wing incidence does not have any effect on the rotor lift or power. Cyclic pitch was not used for trim in any of the calculations. An additional, implicit trim condition for a teetering rotor is that the hub moment must be zero. This condition is normally accommodated by flapping.

Ref. 7 presented correlation of CAMRAD II calculated trim and performance with wind tunnel measurements. While in that work a vortex wake model was used, it was found that the induced drag of both the rotor and wing were small. Hence a uniform inflow model (based on momentum theory) is used for the present results.

#### Comparison of CAMRAD II Model to Simple Analysis

The simplified analysis described above was compared with the rigid blade CAMRAD II model to determine what differences would be introduced by more sophisticated aerodynamics and blade motion, airfoil tables, etc. To model the CCTD using the simplified analysis, a  $\delta_3$  of 10 deg was selected and the Lock number and advance ratio were varied as in the previous results. The stability map for a teetering rotor with 10 deg of  $\delta_3$  is shown in Fig. 7.

Stability calculations were performed for the CAMRAD II model with the rotor trimmed and untrimmed. For the

Fig. 6. Top view of CAMRAD II rotor and wing model,  $\psi = 0$  deg, direction of flight to left.

untrimmed condition, the rotor collective was fixed at 1 deg and the rotor shaft was fixed at 0 deg. The rotor could flap freely and there was no zero torque constraint on the rotor. The tip speed was selected as 230 ft/sec to minimize compressibility effects at high advance ratio. The result is shown in Fig. 8. For the majority of the plot, the damping levels are very similar to those in Fig. 7. At high Lock numbers and advance ratios above 2, the plots begin to differ, as the damping increases in the simplified analysis, but decreases in the CAMRAD II calculation.

The calculation was repeated, enforcing the autorotation condition. Here, the shaft angle was varied to maintain zero power on the rotor. This trimmed result is shown in Fig. 9. Note that the data only extends to an advance ratio of 2. It was difficult to find a stable autorotation condition at the higher Lock numbers. As the advance ratio approached 2, the analysis predicted a rapid change in trim shaft angle, suggesting that the rotor stall was preventing autorotation.

The damping contours for the trimmed case are also similar to the simplified analysis except in the high advance ratio, high Lock number region where the rotor begins to stall. This means that when the rotor is lifting, the damping is unaffected by nonlinear aerodynamics and dynamics, the introduction of a real airfoil, and trim. The simplified analysis is a good approximation for a rigid flapping blade. Note that for a 230 ft/sec tip speed, and advance ratio of 2 corresponds to nearly 275 knots, which is very high speed for a rotary-wing vehicle.

#### Control of Thrust and Autorotation

The performance analysis in Ref. 7 suggested that there was a narrow range of collective pitch where the rotor was autorotating at the desired speed and producing positive lift. The most desirable condition for low vehicle power is for the wing to lift the vehicle and for the rotor to produce no lift and as little drag

Table 2. Properties of the CarterCopter rotor and wing

Fig. 7. Stability map for CarterCopter rotor from simplified analysis,  $\delta_3 = 10$  deg,  $v_\beta = 1.0$  ( $\gamma \approx 2.5$  for CarterCopter).

Fig. 9. Stability map for CarterCopter rotor from CAM-RAD II rigid blade model,  $\delta_3 = 10$  deg,  $v_\beta = 1.0$ , trimmed to autogyro condition.

as possible. Of course, the rotor must produce some thrust in order to maintain autorotation, so a more realistic condition is for the rotor to produce a small positive thrust. Conditions where the rotor produces negative thrust or a significant portion of the vehicle lift are undesirable.

Producing too much lift requires excess power and reduces the vehicle efficiency, but does not prohibit operation. Excessive flapping or control input requirements, however, might prevent the vehicle from operating safely. These represent flying qualities issues if they exceed the abilities of control actuators or of the pilot.

To determine the sensitivity of these variables to collective pitch and advance ratio, the rotor-wing combination described above was trimmed at tip speeds of 230, 345, and 460 ft/sec for several different hub configurations. Teetering, articulated at the root and with a 5% hinge offset, and rigid (no flapping) hub configurations were considered. The rotors were identical in size, planform, etc., to the model in the previous section; only the hub boundary condition was changed.

As in Ref. 7, only lift and rotor power were trimmed for these calculations. The lift of the rotor and wing combination was trimmed to 4200 lb and the rotor torque was trimmed to zero to model lifting the vehicle gross weight and an autorotation condition on the rotor. Trim controls were tilt of the wing and rotor shaft, but there was no cyclic pitch on the rotor. Pitch and roll moments were not trimmed, so the trim conditions for the rigid rotor in particular are not representative of those for a full vehicle.

Before proceeding, an interesting aspect of the autorotation envelope must be discussed. The trim state in autorotation is not unique. Two conditions exist where the rotor can maintain autorotation. To illustrate this phenomenon, isolated rotor power of an articulated rotor with varying shaft angle was considered. Instead of trimming the rotor to zero power, the rotor was not trimmed and instead, the shaft angle was changed. This was intended to determine if the resulting power curve crosses through zero in multiple places.

Fig. 10 shows thrust and power for an articulated rotor hinged at the root at 250 knots and a tip speed of 345 ft/sec. Collective pitch angles of -2, 0, and 2 deg are shown in the figure. The rotor power (solid lines) peaks at different shaft angles depending on the collective pitch. But for each shaft angle, the power curve crosses zero power in two places about 4 deg apart. This means that autorotation can be maintained at either of these shaft angles. In addition, the overlaid rotor thrust (dashed lines) shows that for each collective pitch setting, one trim condition has positive thrust and one has negative thrust. Note that the thrust difference between the two points is on the order of 2000 lbs, a substantial amount for a 4200-lb vehicle.

This raises questions about whether a maneuver could cause the rotor to switch abruptly between the two autorotation points. Transient analysis of a full vehicle is beyond the

Fig. 10. Rotor thrust (open and dashed) and power (closed and solid) for an articulated rotor at 250 knots ( $\mu = 1.22$ ) vs. shaft angle, -2 to 2 deg collective,  $V_T = 345$  ft/sec.

scope of this paper, so this issue is not considered in detail. For the purposes of this paper, the only consequence of multiple trim conditions is that care was taken to always trim to the positive thrust condition. Fortunately, judicious selection of initial conditions was all that was necessary to achieve this requirement.

### Teetering Rotor

The control issue raised in Ref. 7 was based on teetering rotor performance calculations. The lift distributions for the rotor and wing suggested that there was a narrow range of collective pitch settings where the rotor produced an acceptable thrust level. Rotor lift as a function of airspeed and collective pitch for the teetering rotor model is shown in Fig. 11. The contours indicate lines of constant lift and the dashed lines indicate negative lift. From these figures, there does seem to be a small range of acceptable collective pitch. At the lowest tip speeds, Fig. 11a, there is a relatively large range of rotor lift in the 4 deg collective pitch range shown. At 250 kts, the lift changes by approximately 1500 lb over that range. At very high speed, the lift becomes negative for collective pitch settings above 0.5 deg and the range of lift is on the order of the 4200 lb gross weight of the CCTD. Below 250 kts, the desired small positive lift is realized over the entire range.

The 345 ft/sec tip speed case, shown in Fig. 11b shows similar behavior, albeit over a larger collective pitch range. As with the lower tip speed case, the change in lift over the pitch range shown (6 deg for this tip speed) is also about 1500 lb at 250 kts and increases thereafter. Also like the lower tip

(a)  $V_T = 230$  ft/sec

(b)  $V_T = 345$  ft/sec

(c)  $V_T = 460$  ft/sec

Fig. 11. Lift for a teetering rotor vs. airspeed and collective pitch,  $V_T = 230$ – $460$  ft/sec.

speed, there does not appear to be any lift issue for airspeeds below 250 kts.

For the highest tip speed, Fig. 11c, compressibility dominates the vehicle lift above 250 kts. Operating at high airspeeds for this tip speed is not practical due to the high power required (Ref. 7). In summary, while there is the potential for some degradation in performance when operating at a non-optimum collective, small variations will not radically alter the lift on the rotor.

Although the rotor lift was well-behaved over a range of airspeed and collective pitch, large gradients in flapping or controls indicate a handling qualities and perhaps vehicle stability problem. The spindle tilt and blade flapping angles are shown in Figs. 12 and 13. Both the spindle tilt and blade flapping are well-behaved.

The spindle tilt (positive aft) is shown in Fig. 12. It changes with airspeed at low collective pitch, but as speed increases, it is relatively independent of airspeed for all three tip speeds. The reason for this is the vehicle trim. At low speed, the wing (and therefore fuselage) must be at a high angle of attack to carry most of the vehicle weight. As speed and dynamic pressure increase, this angle decreases. For the rotor to maintain its orientation in space, the spindle must be tilted aft to account for the wing angle of attack.

The flapping angle (positive forward), shown in Fig. 13, is also well-behaved. For the 230 and 345 ft/sec tip speeds, the contours are parallel and the range of flapping is about the same as the range of collective pitch. If possible, flapping should be minimized, so for the range of collective pitch settings shown, lower collective pitch is better. For the 460 ft/sec case (Fig. 13c), although the contours are inclined at a steeper angle and the flapping range is slightly larger, there are no steep gradients and the maximum flapping angle is approximately 10 deg. This tip speed is undesirable from a power standpoint, but does not appear to have control or flapping problems.

The orientation of the tip path plane, shown in Fig. 14, is another indication of the state of the rotor. It is the sum of the hub angle of attack and the longitudinal flapping. It only varies over a few degrees for the three tip speeds, but the contours bear some similarity to the contours of lift in Fig. 11. Where the lift increases in Fig. 11, the tip path plane angle increases. The absence of steep gradients indicates that the rotor orientation changes slowly with changes in collective pitch and airspeed.

Finally, rotor power, calculated as rotor drag multiplied by velocity, is shown in Fig. 15. The contributions to drag and power for this rotor are discussed in detail in Ref. 7. For the present study, the only interest is sharp gradients, especially with horizontal contours that indicate rapid changes with collective pitch. In Fig. 15, there are none. The rotor power is nearly independent of collective pitch, so from a power standpoint, any collective pitch setting is appropriate.

(b)  $V_T = 345$  ft/sec

(c)  $V_T = 460$  ft/sec

(c)  $V_T = 460$  ft/sec

Fig. 14. Tip path plane angle of attack for a teetering rotor vs. airspeed and collective pitch,  $V_T = 230$ – $460$  ft/sec.

Fig. 15. Power required for a teetering rotor vs. airspeed and collective pitch,  $V_T = 230$ – $460$  ft/sec.

This is consistent with findings for a single collective pitch setting in Ref. 7 that power was dominated by profile power and interference and induced power were minor in comparison. Because the lift is strongly dependent on collective pitch in Fig. 11, but the power is not, the induced power must be small relative to the profile power on the rotor. Given this, it is not a detriment for the rotor to carry lift.

These results provide guidance for an optimum collective pitch. The first clear conclusion is not to use the 460 ft/sec tip speed. The increased power required is clearly undesirable. For the lower tip speeds, the lift gradients do not translate into gradients in rotor power, so the optimum collective can be chosen based on control and flapping angles. These results, Figs. 12–13, oppose each other. Spindle tilt is minimized as collective pitch increases, but flapping is minimized for lower collective pitch. Therefore a moderate value in the 0–1 deg range is appropriate.

### Articulated Rotor

The previous section described control calculations for a teetering rotor. The same results for an articulated rotor hinged at the center of rotation are shown in Figs. 16–20. The model used to calculate these results is the same as the teetering rotor except that the blades can now flap independently. The results for the 230 and 345 ft/sec cases are indeed very similar to those for the teetering rotor. The rotor lift, Fig. 16, increases at low collective pitch angles and high speed, and decreases to the point of being negative at high collective pitch angles and high speed. The 460 ft/sec articulated case is also quite similar to the 460 ft/sec teetering case.

The flapping, spindle tilt, and tip path plane angle are also similar to the teetering rotor. The flapping angle (Fig. 17) decreases with positive collective, and the spindle tilt (Fig. 18) decreases with negative collective. The change in slope of the contour lines between the 345 and 460 ft/sec tip speed cases is also present. The tip path plane angle tracks the rotor lift as well, and no steep gradients are present.

The power plots (Fig. 20) also look similar to those for the teetering rotor, except the power differences between the tip speeds are more pronounced. In Fig. 15, the differences between the 230 and 345 ft/sec tip speed cases were hardly noticeable. In Fig. 20, the differences are still not large but it is clear that the power is higher for the 345 ft/sec tip speed case. The power required for the 460 ft/sec tip speed case is significantly higher than that for the 345 ft/sec tip speed, again indicating that the rotor should not be operated at this speed.

The conclusion is that the optimum collective pitch should be in the middle of the collective range, although the power curves suggest that a bias toward lower collective pitch would reduce the power required by the rotor. Depending on the maximum speed for the vehicle, this would require a spindle tilt of 7–8 deg, which should be a tolerable control angle.

Fig. 20. Power required for an articulated rotor hinged at the center of rotation vs. airspeed and collective pitch,  $V_T = 230$ –460 ft/sec.

Figs. 21–25 show results for an articulated rotor with a 5% hinge offset. For this model, the pitch horn was moved with the flap hinge and pitch bearing so that there was no  $\delta_3$  coupling in the rotor. The contours for lift, flapping, spindle tilt, tip path plane angle, and power are almost identical to those for the articulated rotor with no hinge offset. While specific discussion of the results need not be repeated, the observation that the results are insensitive to hinge offset is noteworthy.

### Rigid Rotor

The last case to be examined for handling qualities and control issues was a rigid rotor. For this case, there was no articulation or blade motion whatsoever, so the rotor is more representative of a propeller. The vehicle roll moment was not trimmed with cyclic, so this condition is more for academic than practical interest.

The rotor lift is shown in Fig. 26. Unlike the previous cases, the differences are very pronounced between the three tip speeds. The contours are approximately parallel between the three tip speeds, but the magnitude of the gradient is very different. For example, at a collective of 1 deg, for the 230 ft/sec case, lift varies from about 750 to 2000 lb. For the 345 ft/sec case it varies from about 1200 to 3000 lb of lift (from 125–300 kts), and for the 460 ft/sec case, the range is about 2000–5000 lb. Note that lift above 4200 lb (heavy lines in Fig. 26) exceeds the vehicle weight and results in the wing producing negative lift to maintain steady flight.

For the rigid rotor, there is no flapping, but the spindle tilt is shown in Fig. 27. As the tip speed increases, more spindle tilt is required to maintain autorotation. Depending on the tip speed and the amount of tilt available, the maximum flight speed may be limited. The rotor cannot flap, so the only variable controlling the tip path plane relative to the oncoming wind is the spindle tilt. Because the required spindle tilt is nearly insensitive to collective pitch, optimum collective pitch should be based on power required.

The tip path plane angle (Fig. 28) mirrors the rotor lift for the three tip speeds, except that the contours become enclosed at low airspeed. The rigid rotor carries more lift at low speed than the other configurations, so more aft tilt of the disk plane is required to generate the additional lift at reduced dynamic pressure.

The power required is shown in Fig. 29. Like the previous hub configurations, the power does not vary appreciably with collective pitch. There is, therefore, some latitude in selecting a collective pitch angle for cruise.

In summary, there do not appear to be any significant flying qualities or performance issues related to collective pitch. Depending on the tip speed and the design cruise speed, some benefit can be realized by careful selection of collective pitch, but adequate performance and controllability is possible over a range of collective pitch settings.

## Elastic Blades

A generic CAMRAD II elastic blade model was developed to determine what effect elasticity has on stability. Structural dynamic properties for a production blade are preferable, but elastic properties for a high advance ratio rotor were not available. Instead, elastic properties were chosen to approximate what a production blade might have.

The model was intended to be as simple as possible. The blade has no chordwise offsets of center of gravity, tension center, etc., and uniform stiffness. The blade frequencies were designed based on a hover tip speed of 650 ft/sec. The flap and lag stiffness values were adjusted for a fundamental lag frequency near 1.2/rev and ratio of lag to flap stiffness of 30:1. Three separate torsion stiffness values were selected for comparison. They were chosen to produce fundamental torsion frequencies of 4.5/rev, 6.5/rev, and 8.5/rev at a 650 ft/sec tip speed.

A fan plot for the elastic blade model is shown in Fig. 30. The operating speeds and the speed at which the frequencies were set are shown by solid lines at 100, 150, 200, and 282 RPM. The solid symbols are flap and lag modes for the 4.5/rev torsion frequency. The flap and lag modes for the 6.5/rev and 8.5/rev torsion frequencies were the same to the resolution of the plot, so they were not duplicated. The three torsion modes are plotted on the same graph with open symbols, but it is important to realize that only one of the torsion modes is present in each model. Since the torsion modes do not vary with RPM, the torsion frequencies at the operating speeds of 230–460 ft/sec are higher.

The stability of the elastic blades is shown in Figs. 31–33. Four modes were used in the elastic blade analysis, one each of teeter, elastic flap, lag, and torsion. The rigid blade teetering mode damping (the only degree of freedom for the rigid blade model) is also shown on the plots for comparison. For these results, the models were trimmed to zero power by tilting the shaft. The lowest tip speed of 230 ft/sec was chosen to eliminate the effects of compressibility. Once the trim condition was satisfied, Floquet theory was used to calculate system eigenvalues. The modes were identified by matching the frequency and damping to form continuous curves. The damping level shown is the real part of the eigenvalue, so negative numbers are stable, positive numbers unstable.

A hard stability boundary is evident near an advance ratio of 1.5 in Figs. 31–33. Although it appears from the plots that different modes become unstable, but at this boundary several modes become unstable at once. The modes become unstable very rapidly, so it is difficult to obtain a periodic solution and the damping levels (both stable and unstable) in this region are very sensitive to small changes in the trim state. Regardless of the damping levels, it is clear that the rigid blade shows no sign of instability while the elastic blades are clearly unstable and the stability boundary does not depend on the torsion frequency.

Fig. 30. Frequencies of the CAMRAD II elastic blade models with 4.5–6.5/rev torsion frequencies.

Fig. 31. Stability of elastic teetering rotor at tip speed  $V_T = 230$  ft/sec and torsion frequencies of 4.5/rev.

Fig. 32. Stability of elastic teetering rotor at tip speed  $V_T = 230$  ft/sec and torsion frequencies of 6.5/rev.

Fig. 33. Stability of elastic teetering rotor at tip speed  $V_T = 230$  ft/sec and torsion frequencies of 8.5/rev.

Fig. 34. Comparison of rotor lift for elastic and rigid blade teetering rotors,  $V_T = 230$  ft/sec and elastic torsion frequencies of 6.5–8.5/rev and rigid.

The elastic stability is very different from the rigid blade stability in Figs. 8 and 9. For the rigid blade, the rotor is stable to an advance ratio of 3, but for the elastic blade, there is a sharp stability boundary at an advance ratio of about 1.5. This reinforces the importance of elastic blade properties and shows that even for a teetering rotor, if the blades are not sufficiently stiff, an instability will occur.

The rotor thrust and power for these rotor models are shown in Figs. 34 and 35. These show that although there is a large difference in stability, there is almost no difference in performance. In Fig. 34, the lift for the 4.5/rev torsion frequency appears to deviate significantly from the other frequencies and the rigid blade. The approximately 200 lb of difference in lift represents only about 5% of the vehicle gross weight, so the deviation is actually small. When the torsion frequency is raised to 6.5/rev, the lift is nearly converged to the rigid blade result. The rotor power is dominated by profile power, so this deviation is almost imperceptible in Fig. 35. These results suggest that stability boundary is not caused by changes in the trim state resulting from elastic deflections, but is very sensitive to elastic stiffness.

### Conclusions

The stability and control of rotors at high advance ratio applicable to a slowed-rotor compound helicopter have been investigated. A simple linear model, rigid blade CAMRAD II

Fig. 35. Comparison of rotor power for elastic and rigid blade teetering rotors,  $V_T = 230$  ft/sec and elastic torsion frequencies of 6.5–8.5/rev and rigid.

models, and an elastic blade CAMRAD II model were developed. The following conclusions are made:

1. The simplified flapping blade analysis suggested that a teetering rotor was the most stable hub configuration. The articulated rotor was unstable above an advance ratio of about 2.2 but could be stabilized to higher speed with  $\delta_3$ . The gimballed rotor was unstable above advance ratios of about 2 and was not stabilized by  $\delta_3$ .
2. Damping predicted by the simplified analysis and a rigid blade CAMRAD II model were similar outside regions of rotor stall. Trimming the CAMRAD II model to an autorotation condition did not influence the stability.
3. Autorotation can be maintained at two distinct shaft angles for the same collective pitch setting. For one shaft angle, the rotor produces positive lift, for the other, negative lift.
4. The optimum collective pitch for the four hub configurations—teetering, articulated with 0% and 5% hinge offset, and rigid—was found to be around 0–1 deg to minimize control input and flapping. There was no collective pitch restriction on power for the collective pitch ranges considered.
5. Rotor power required was only increased slightly by increasing the tip speed from 230 to 345 ft/sec, but a large increase was seen increasing from 345 to 460 ft/sec.

6. Blade elasticity was found to drastically reduce the rotor stability. For the particular blade stiffnesses considered, a sharp boundary was predicted near an advance ratio of 1.5. The blade elasticity did not significantly affect the rotor performance.
